ABSTRACT

Acid rain is a worldwide environmental problem that started in industrialized countries, and it has been extended to underdeveloped countries. Actions must be taken, and one of those is to deal with one of the major SO_2 emission sources that are thermal power plants. A way of decreasing the SO_2 emissions is to treat the flue gases with sorbent materials, which selectively trap the SO_2 . These materials may be based on calcium and many efforts have been recently performed in order to increase their activity and yield. In the present work, SO_2 sorbent materials, based on $\text{Ca}(\text{OH})_2$ at different mass ratios, were prepared supported on clays (bentonite and tonsil), and their activity was tested in a thermogravimetric balance. In addition, ultrasonic energy was applied during preparation trying to improve their performance. It was found that activity increased proportional to the Ca load. Also, when temperature increased from 350 to 450°C, the SO_2 sorption capacity increased. The support clays did not play an important role; at low temperature, activity was slightly better in materials supported on tonsil, but as temperature increased the yield of materials supported on bentonite surpassed those of material supported on tonsil. Ultrasonic energy did not improve the performance of sorbent materials, and, in fact, the sorption capacity diminished when ultrasonic energy was applied during preparation of materials. Finally, the SO_2 sorption process was modeled using a modified shrinking core approach and kinetics parameters were estimated.

Keywords: acid rain, $\text{Ca}(\text{OH})_2$, tonsil, bentonite, sorbent materials, flue gas desulfurization, ultrasonic energy, kinetics parameter estimation

1. INTRODUCTION

The combustion of fossil fuel for the generation and/or transformation of energy in sectors, such as, industry, transport and commercial has caused an increase in the concentrations of gaseous and particulate pollutants in the atmosphere. This increase in pollutants has resulted in air pollution. One of the most critical environmental problems is the acid rain, which is a broad term that describes several ways through which acid falls out, including acidic rain, fog, hail and snow. At the beginning of the problem, acidic rainfall was commonly detected around industrial areas; however, with the increased use of tall stacks for power plants and industries, atmospheric emissions are now transported beyond the industrial areas. Acid rain is the result of many steps of chemical reactions between air borne pollutants (oxides of sulfur, nitrogen and other constituents present in the atmosphere) and atmospheric water and oxygen. Main sources of these oxides are fossil fuel fired power stations and smelters for SO_2 , and motor vehicle exhausts for NO_x . These oxides may react with other chemicals and produce corrosive substances that are washed out either in wet or dry form by rain as acid deposition [1-3].

Comment [HSMD1]: Wrong format. Please indicate aims, study design, methodology, results, conclusions, place and duration of study.

34 Acid rain has several effects in the ecosystem, which include the decay in growth of trees,
35 crops, aquatic flora and fauna. In addition, soil fertility is deteriorated as a result of leaching
36 of nutrient cations and the increased availability of toxic heavy metals. Also, stones, metals,
37 paints, textiles and ceramics can be eroded and corroded due to acid rain. It can also
38 indirectly affect human health since it has been shown that SO_2 and NO_x contribute to the
39 formation of $\text{PM}_{2.5}$ [3-6]. The acid rain problem has been tackled to some extent in
40 developed countries by reducing the emission of the precursor gases, and several actions
41 have been created in different parts of the world i.e., the Gothenburg Protocol for the
42 European Union and the US Acid Rain Program in the Title IV of the 1990 Clean Air Act
43 Amendments. [7-10].
44 Due to the rapid economic development and energy consumption throughout the world,
45 fossil fuel consumption has significantly increased during the last few decades. The use of
46 fossil fuel is the major cause of large-scale generation of acid precursors in the atmosphere.
47 The problem was originally identified as an issue in developed countries, but with the
48 increase in industrialization and urbanization, developing countries are now also
49 experiencing this issue.
50 Many reviews have been published related to commercial and pilot-plant technologies for the
51 abatement of SO_2 from thermal power plants [11-13]. Most of the probed technologies are
52 based in calcium sorbents, such as, $\text{Ca}(\text{OH})_2$ and CaO , either in wet or dry conditions. New
53 research efforts have been addressed to improve the yield of calcium materials as SO_2
54 sorbent by mixing it with several supports, such as, silica, fly ash, blast furnace slag, clays,
55 and activated carbon [14-21]. In the present work $\text{Ca}(\text{OH})_2$ was mixed with bentonite and
56 tonsil at many mass ratios. These clays were chosen because they are abundant in Mexico
57 and can be considered a local low-cost raw material, which would reduce the operating cost
58 if they were applied in a local power plant. Bentonite is an aluminiumhydrosilicate, in which
59 the proportion of silicic acid to alumina is about 4:1. On the other hand, tonsil is created from
60 bentonite by acid activation. During this activation, the individual layers are attacked by the
61 acid; as result, aluminum, iron, calcium and magnesium ions are released from the lattice.
62 Also, in a way for further improvement the performance of the sorbent materials, ultrasonic
63 energy may be applied during preparation in an effort to reduce the particle size and
64 increase available active sites as it has occurred in other materials [22-26].

65
66

67 **2. MATERIAL AND METHODS**

68

69 **2.1. Sorbent Preparation**

70

Samples of $\text{Ca}(\text{OH})_2$ supported in bentonite and tonsil were synthesized by preparing
71 slurries at different mass ratio. Some of them were mechanically stirred during 4 h at 60-
72 70°C. In other slurries, ultrasonic energy was applied during 4 h maintaining the temperature
73 below 70°C. After the mixing, slurries were dried overnight a 120°C and pulverized.

74

75 **2.2. Sorbent characterization**

76

To determine the actual calcium content, samples of the sorbent-materials were analyzed by
77 Atomic Absorption Spectroscopy. Table 1 presents the composition of the different materials.

87

2.3. Sulfation of sorbents

88

89 The sulfation of the materials was carried out in a thermogravimetric balance (TA
90 Instruments 2050) by passing a stream of certified 3600 ppm_v SO₂/N₂ through a known
91 amount of sorbent material. The gas flow rate was 100 mL/min, which is the maximum flow
92 of the thermobalance. The gain of weight in the material was assigned to the sorption of SO₂
93 on the active sites. **To ensure reproducibility of the results, the analyzer is monthly calibrated
94 according to international standards by a certified agency.**

94

95

3. RESULTS AND DISCUSSION

96

97

3.1. Sorption of SO₂ on bentonite and tonsil

98

99 Experiments in the TGA varying temperature (heating rate: 10°C/min) were performed to
100 check if supports were able to adsorb SO₂. Results are presented in Fig. 1, and it was
101 observed that none of the clays retained SO₂. In fact, it was noticed that weight loss
102 occurred as the temperature increased; however, this is attributed to a loss of humidity in the
103 interval between room temperature and 120°C. Then, a drastic weight loss was observed,
104 especially in bentonite, at temperatures higher than 550°C; this is a result of the thermal
105 rearrangement of the crystalline structure.

106

107
 108 **Figure 1. Thermogravimetric profiles of the supports in the sulfurization process at**
 109 **variable temperature.**

110
 111
 112 **3.2. Effect of temperature in the sorption capacity**

113 To determine the temperature interval in which the sorbents were studied, an experiment in
 114 the TGA with pure Ca(OH)₂ at heating rate of 10°C/min was performed. The result is shown
 115 in Fig. 2. It is observed that the SO₂ sorption process begins at 300°C, and it continues up to
 116 650°C. At temperature interval of 420-480°C is noted a drastic loss of weight, but it can be
 117 assigned to Ca(OH)₂ decomposition to form CaO, which is also active for adsorbing SO₂.
 118 Finally, the selected temperature interval was 350-450°C since at this temperature interval
 119 the flue gases enter and exit the preheaters in a thermal power plant, and the proposed
 120 technology would be installed at this point.
 121

122
123 **Fig. 2. Thermogravimetric profiles of pure Ca(OH)₂ in the sulfurization process at**
124 **variable temperature.**

126 Experiments were carried out at constant temperature for 90 min and the amount of SO₂
127 sorbed in the prepared materials is presented in Fig. 3. It is clearly noticed that as the
128 temperature increases, the sorption capacity of the materials is enhanced. This effect is
129 observed in all materials regardless of the support, Ca load, or preparation method.
130

Fig. 3. SO₂ sorption capacity of the different prepared materials at 90 min.

3.3. Effect of calcium load

According to the results presented in Fig. 4, Ca load plays an important role in the sorption capacity of the prepared materials as it has been previously reported [Liu et al., 2004; Macias-Perez et al., 2007; Lin et al., 2003]. At lower temperature (350°C) the effect is not well-defined, but as the temperature increases it is observed that Ca load enhances this property. For instance, at 450°C, and considering the material supported on tonsil and prepared with mechanical stirring, at Ca load of 31 wt%, the sorption capacity is 27 mg/g, but as the Ca load increases to 52 wt% (1.7 times), the sorption capacity rises up to 98 mg/g, which is 3.6 times more than at 31 wt%. Moreover, when Ca load is 68 wt% (1.3 times with respect to the last load), the sorption capacity increases 2 times compared to the last load, sorbing 194 mg/g. These results are unexpected; it seems that supports (either tonsil or bentonite) are blocking the active sites instead of providing better dispersion and more active sites. Similar results were previously reported in materials supported on fly ash at low Ca loads [27].

Fig. 4. Effect of calcium load in the SO₂ sorption capacity of the prepared materials.

3.4. Effect of support

The type of support did not show a trend, considering the results presented in Fig. 3. Data suggest that at low Ca loads the materials supported on tonsil result in slightly better yields, but as temperature and Ca load increased this tendency disappears, and finally, at higher temperature (450°C) and Ca load, the better performance was obtained for the material supported on bentonite regardless of preparation method.

3.5. Effect of preparation method

Ultrasonic energy was used trying to improve the yield of the proposed materials. Since the application of ultrasonic materials in slurries is able to fragment the solid particles, decreasing their size, it is proposed that this event would multiply the number of available active sites for the SO₂ sorption process. Nevertheless, the results presented in Fig. 3 do not show an improvement in the performance of the prepared materials. In fact, it is observed that the efficiency of the materials declines when ultrasonic energy is applied during their preparation. This result is attributed to a fusion of the Ca particles when they collide during the application of ultrasonic energy. One of the theories of the particle fragmentation during ultrasonic energy application explains that particles in the slurry are accelerated, and when a collision occurs, they break. Nevertheless, in soft materials, which would be the case of Ca(OH)₂, when the collision happens, the particles are fused, so the particle size increases, and in the case of the present work, would diminish the available active size for the SO₂ sorption process.

3.6. Kinetics parameter estimation

Several models have been developed to represent the heterogeneous non-catalytic solid-gas reaction; however, the most popular used to describe the sulfation of solid sorbents are based on the shrinking core process [28-33]. In this model, it is considered that a first-order chemical reaction between the SO₂ and the calcium core of a spherical particle happens first in the outside surface of the particle forming CaSO₃/CaSO₄. Then, the reaction zone is moved inside the sorbent, leaving behind a converted material and inert solid called “ash” that gradually expands blocking and plugging the pores of the sorbent material because the molar volume of CaSO₃/CaSO₄ is higher than that of CaO or Ca(OH)₂. In this way, there is an inert layer shrinking during the chemical reaction. The relationship between the time and the covered fraction depends on the rate-limiting step. In order for the reaction to proceed, the SO₂ has to diffuse into the new layer, and it has been shown that rate-limiting step for sulfur uptake is the diffusion of SO₂ through the pores of the new product layer on the particle surface [34]. Therefore, the kinetics model that represents the SO₂ sorption process is

$$\frac{t}{k} = \left[3 - 3(1 - \theta)^{2/3} - 2(1 - \theta) \right]$$

$$k = \frac{\rho_B \cdot R^2}{6 \cdot b \cdot D_e \cdot C_g}$$

192 Where: θ is the covered fraction, ρ_B is the molar density of the active sites in the solid, b is
193 the molar ratio of solid reactant to gas reactant (ratio of stoichiometric coefficient), R is the
194 radius of unreacted core, k is the kinetics constant for the surface reaction, C_g is the SO₂
195 concentration in the flue gas, D_e is the effective diffusion coefficient of SO₂ through the “ash”.
196 To improve the adjustment, it was assumed that the SO₂ effective diffusion coefficient, D_e ,
197 depends on the conversion since the new product layer modifies the SO₂ diffusion
198 characteristics through the sorbent material:

$$D_e = D_{e0} \cdot [1 + \alpha_1 e^{(-\alpha_2 \cdot \theta)}]$$

199 Non-linear regression analysis was performed using Polymath™ to determine the kinetics
200 parameters and the results are shown in Tables 2 and 3. According to these results, a good
201 fit was obtained since the R^2_{adj} was high, and with a few exceptions, it was greater than
202 0.99. It is interesting to notice that α_2 takes negative values depending on the calcium load
203 since materials with relationship 1:1 and 2:1 Ca:support, α_2 is negative. This may be
204 assigned to the Ca species formed during sulfation (CaSO₃ or CaSO₄) and their tendency to
205 modify the D_e during the process. A negative α_2 indicates that D_e is not considerable affected
206 by conversion. Fig. 5 and 6 present the fit between the experimental data and the proposed
207 model.

To determine the dependency of the diffusion coefficient, D_{e0} , with respect to temperature, it is necessary to point out that it cannot be directly determined because ρ_B and R , which are other physical parameters involved in k , were not experimentally determined. However, some trends with respect to temperature, support, and preparation method are detected. First, it is critically important to emphasize that if the numerical value of k decreases, it

223 implies that D_{e0} increases since the other parameters are constant, and vice versa, an
 224 increase of k means a reduction in the diffusion coefficient. It is observed that in all the
 225 prepared materials (regardless the support, Ca load, or preparation method) as temperature
 226 increases the value of D_{e0} also raises. So, an Arrhenius-type dependence with respect to
 227 temperature can be obtained. Activation energy was calculated and is presented in Tables 4
 228 and 5. In some cases, confidence limits are quiet high, but they are still statistically
 229 acceptable. These variations may be attributed to the Ca species that are formed during the
 230 reaction. At low Ca loads the activation energy of material supported on tonsil is smaller
 231 compared to those supported on bentonite; however, when increasing the Ca load, the
 232 activation energy of material supported on bentonite is less when ultrasonic energy is
 233 applied during preparation method. This confirms the previous statement that materials
 234 supported on bentonite give better results as the Ca load and temperature augments.

4. CONCLUSION

278 Materials based on Ca(OH)₂ and supported on bentonite and tonsil were prepared at
279 different mass ratios and tested in a thermogravimetric balance to determine their SO₂
280 sorption capacity. These materials were active for the desulfurization of flue gases, and their
281 activity was improved as the calcium load and temperature increased. On the other hand,
282 support was not important since the activity was almost the same at different experimental
283 conditions; however, at low temperature activity was slightly better for materials supported
284 on tonsil, but those supported on bentonite gave better results as the Ca load and
285 temperature increased. When ultrasonic energy was applied during the preparation of the
286 sorbent materials, their activity decreased, and it was attributed to an agglomeration of Ca
287 particles, so the available active sites decreased. The SO₂ sorption process was
288 represented by a modified shrinking core process model, and the kinetics parameters were
289 estimated using Polymath™. It was found that the effective diffusion coefficient increased
290 with temperature. Activation energy of materials supported on bentonite was greater at low
291 Ca load, but as this load increased, their activation energy was smaller compared to
292 materials supported on tonsil.
