2 REVIEW OF ANTIBIOTICS USAGE IN THE MANAGEMENT OPEN

3

1

FRACTURE IN A NIGERIAN HOSPITAL

4

5 ABSTRACT

BACKGROUND. Antibiotics are adjuncts in the management of open fractures, and microbial characteristic of open fractures will guide the use of antibiotics. With changing pattern in microbial colonization of wounds, the need to review antibiotic usage in hospitals becomes imperative. The study aimed to evaluate the antibiotic protocol of managing open fractures at the Accident and Emergency department, with the advent of new antibiotics introduced into the hospital drug formulary.

MATERIALS AND METHODS. This study is a hospital-based prospective evaluation of the antibiotic sensitivity of cultured microorganisms from the patients with open fractures presenting between January 2013 and December 2013 in the Accident and Emergency Department, of a tertiary hospital in Nigeria. Swabs of superficial and deeper parts of the wound were taken at the presentation of the patients before wound debridement and commencement of antibiotics. Other two samples and biopsies were taken at the deeper parts of the wound on the 3rd and 7th day of admission. Culture and Sensitivity pattern of isolates were determined for positive cultures using antibiotics impregnated disks. Descriptive and inferential statistics of the findings are presented.

RESULT. One hundred and thirty patients were recruited for the study, a sterile swab was taken from their wounds at presentation, but 81 patients completed the study. Forty patients discharged themselves against medical advice and while nine patients were referred to other hospitals. *Staphylococcus aureus* and *Clostridium perfringens* was the most common aerobic and anaerobic isolates respectively. The aerobic isolates and anaerobes were susceptible to ceftriaxone, ciprofloxacin, co-Amoxyclav, gentamycin, and cefotaxime and metronidazole respectively.

CONCLUSION. The antibiotic sensitivity pattern in the emergency department of the Hospital has changed not significantly as previously reported about 12 years earlier. Therefore, the hospital antibiotic protocol in the treatment of open fractures in the Accident and Emergency department should be retained.

7 Introduction

Comment [Office1]: Management of open fractures

Comment [Office2]: Rephrase statement

Comment [Office3]: were

- 8 The choice of antibiotics in the treatment of open fractures as an adjunct to debridement and
- 9 wound care is determined by established microbial characteristics of open fractures in the
- 10 locality or empirically using combination therapy to cover most of the available organisms
- 11 such as Gram-positive and Gram-negative aerobes as well as the anaerobes. The trend of
- 12 microbial infections and antibiotic sensitivity pattern in the hospital where this particular
- 13 study was undertaken had been established by a previous study [1] The choice of antibiotics
- in the treatment of infections is determined by the potential bacterial contamination based on
- 15 historical or research documented patterns for each locality [2]. On account of their findings,
- 16 Wilkins and Patzakis recommended the use of a combination of cephalosporins, penicillins
- 17 and aminoglycosides in open fractures depending on the severity of the wound and extent of
- 18 contamination [3]. However, Alonge et al. in Ibadan Nigeria, found that pefloxacin,
- 19 ciprofloxacin and ceftriaxone were the antibiotics which exhibited relatively higher
- 20 sensitivity to the micro-organisms isolated [1], which is in agreement with the findings in
- 21 other studies [4] [5] [6] [7][8].
- 22 An open fracture can be defined as a break in the structural continuity of a bone in which the
- 23 fracture hematoma communicates through the soft tissue with epithelial lining including skin
- 24 and mucosal lining. It is relatively common especially in developing countries and accounts
- 25 for a third of all trauma referrals [1]. In one study, Forty-eight percent of fractures were open
- 26 fractures with a preponderance for males and a predilection for the tibia and the forearm
- 27 bones [9]. Open fractures usually result from high energy trauma such as motor vehicle
- crashes, falls from height, gunshot injury, assault and machine injury [5] and are prone to
- 29 contamination and infection[4]. Open fractures have been classified into three major types (I,
- 30~ II, III) and type III has been further sub-classified into three groups, based on the mechanism
- 31 of injury, the degree of soft tissue damage, the configuration of the fracture and the level of
- 32 contamination [2] [10]

33 Decades of research correlating the Gustilo-Anderson types and the risks of infection have

- 34 helped refine surgical protocols, change in antibiotic prescriptions, and in defining the
- 35 appropriate timing for interventions including debridement, modalities of fracture fixation,
- and soft tissue coverage [11][12][13][14][15][16]. Infections in open fractures often develop
- 37 after six hours of injury if adequate surgical treatment is not carried out along with the
- 38 administration of appropriate antibiotics early enough after the injury. Deep fracture site
- 39 infections could lead to complications of chronic osteomyelitis, nonunion and sometimes
- 40 limb loss. Apart from the exposure of the fractured bone, numerous predisposing factors
- 41 which influence the development of infection include shock from blood loss, hypoxia and the
- 42 degree of communition [17]. Majority of infections in open fractures are caused by
- 43 Staphylococci species especially Staphylococcus aureus and coagulase-negative
- 44 Staphylococci, gram-negative bacilli which include Acinetobacter spp, Escherichia coli,
- 45 *Pseudomonas* spp, *Klebsiella* spp and *Proteus* spp amongst others[4][14][17]. However,
- 46 Alonge et al. in 2002 established that E coli was the most prevalent single isolate while
- 47 *Staphylococcus aureus* was the most prevalent microbial isolate in poly-microbial infections48 [1].

Comment [Office4]: wound care,

Comment [Office5]: research,

- 49 While antibiotics have been established as an essential adjunct in the treatment of open
- 50 fractures, resistance to available antimicrobial drugs is an established and ever-growing
- 51 challenge in clinical practice. Such resistance can result from two mutually non-exclusive
- 52 phenomena: mutations in house-keeping structural or regulatory genes and the horizontal
- 53 acquisition of foreign genetic information [18]. Outbreaks of infections due to Klebsiella
- 54 pneumonia harboring plasmid-encoded cephalosporinases and the spread of this resistance
- 55 mechanism to bacterial species naturally susceptible to cephamycins have been reported [19].
- 56 An infection engrafted on a biomaterial (thick, adherent biofilm) responds poorly to
- 57 antimicrobial therapy and usually is not cured until the biomaterial is removed. Bacterial
- isolates may not be entirely representative of the microbial components of the biofilm
- 59 because the coherent properties of the adherent biofilms that are found on surfaces in these
- 60 infections may prevent genuinely representative organisms from detaching in sufficient
- 61 numbers to be detected entirely and consistently by simple sampling and routine culture
- 62 techniques. Therefore, antimicrobials that are chosen from the culture results may not be
- 63 effective against all of the bacterial species in these biofilm infections [20].
- 64 The rapid spread of antimicrobial resistance in a wide variety of bacteria is mainly due to the
- 65 location of antimicrobial resistance genes on mobile genetic elements such as plasmids and
- 66 transposons [21]. Globally, Enterobacter isolates resistant to expanded-spectrum
- 67 cephalosporin is becoming a matter of concern for the possibility of transmitting
- antimicrobial resistance from one microorganism to another [22].
- 69 This study aimed to review the antibiotic treatment protocol for open fractures in the A&E of
- 70 a tertiary hospital in Nigeria with the view for recommendations for possible change in
- 71 practice.
- 72

73 MATERIALS AND METHODS

- 74 This study is a hospital-based prospective evaluation of antimicrobial pattern and antibiotics
- 75 sensitivity pattern in open fractures presenting in the Accident and Emergency Department of
- the University College Hospital, Ibadan from January 2013 to December 2013.
- 77 Proforma for the study was completed for all patients seen in the Accident and Emergency
- 78 department of the hospital with open fracture after obtaining securing informed consent from
- 79 the included patients. Patients with an open fracture who had wound debridement and
- antibiotics before presenting at the Accident and Emergency of the University College
- 81 Hospital, Ibadan were excluded.
- 82 Poly-traumatized patients with concomitant open fractures were resuscitated and treated
- using the advanced trauma life support (ATLS) protocol. The associated wounds with open
- 84 fractures were inspected, and clinical photographs obtained to record the injury at
- 85 presentation. Four sterile wound swabs, (superficial aerobic and anaerobic, deep aerobic and
- anaerobic) were collected from the superficial and deep parts of open fracture wounds using
- 87 the Levine's technique. The swabs of the wounds were obtained aseptically before wound

Comment [Office6]: Mention details of the ethical approvals sought prior to study commencement.

Comment [Office7]: Were these patient included for the study?

88 debridement and antibiotics were commenced within 30 minutes of patient's arrival at the

89 Accident and Emergency Department. Two other samples and biopsies were taken at the

90 deeper parts of the wounds on the 3^{rd} and 7^{th} day of admission. Samples were collected into

91 sterile Stuarts transport medium, and sterile Robertson cooked meat medium for aerobic and 92 anaerobic organisms respectively. The samples were labelled "S" for superficial swab

samples, "D" for deep swab samples, "BS" and "BD" for superficial and deep biopsy samples

94 with the patient's research number on the laboratory request form and also on the bottle. All

samples arrived the laboratory within 30 minutes to 3 hours of collection. The samples were

96 stored at room temperature in a cupboard for less than 6 hours until ready for analysis.

97 Microscopy, culture and sensitivity patterns of the samples to various antibiotics (penicillin,

98 cephalosporin, quinolone, aminoglycoside, clindamycin, sulphonamides and trimethoprim,

and metronidazole) were carried out. The samples for aerobic cultures were plated out on

sterile Sheep blood agar and MacConkey agar aseptically and incubated at 37^oC for 24 hours.

101 The direct Gram staining of the swabs was carried out, and the slides examined to identify the

102 presence of organisms and pus cells. After 24 hours of incubation, the plates were analyzed

103 for the growth of the bacteria and gram staining of the bacteria colonies were carried out.

104 The confirmatory test of all the isolated gram-negative bacilli was based on the use of API 20

105 E while the gram-positive cocci were based on the use of control organisms for coagulase

106 test. Sensitivity testing was carried out using the disc diffusion technique (Bauer Kirby

107 method), where the Mueller Hinton agar was seeded with the confirmed bacteria, and the

108 observed zone of inhibition around the antibiotic discs was measured and compared with the 109 controlled organism. It was recorded as sensitive if the observed area was greater or equal to

109 controlled organism. It was recorded as sensitive if the observed area was greater or equal to 110 the zone of the controlled microorganisms and resistant if less than the observed zone of the

standard organisms. The anaerobic samples were inoculated aseptically into a sterile Sheep

blood agar and MacConkey agar within five minutes of sample collection. The inoculated

plates were incubated in the anaerobic gas chamber containing anaerobic catalytic agent.

114 Anaero Gen kit and anaerobic control kit (Oxoid Ltd of United Kingdom). Strict anaerobic

115 control bacteria and strict aerobic bacteria were also included as an added quality control.

116 The anaerobic organisms were left in the chamber to incubate at 37^{0} C for three days to isolate

the fast-growing anaerobes which are mostly contaminants while the late growing anaerobes

118 were further incubated for ten days and these are the bacteria of medical importance.

119

120 RESULTS

121

Eighty-one of the 130 patients recruited completed the study with superficial and deep swab samples taken from all patients on the first day and the second and third swab and biopsy samples taken on the third and seventh day of admission. Forty patients took their discharges

against medical advice while nine patients were referred to other hospitals of their choice.

126 Eight of the open fractures were excluded based on the study exclusion criteria. There were

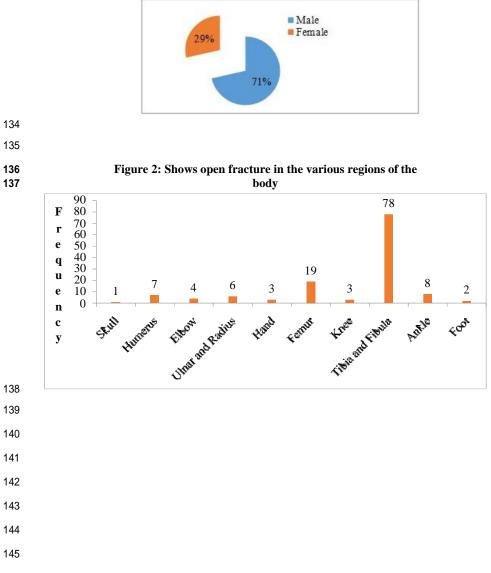

127 93 (71.5%) male and 37 (28.5%) female patients as shown in figure 1 while figure 2

128 represents open fractures in different regions of the body with the tibia and fibula constituting

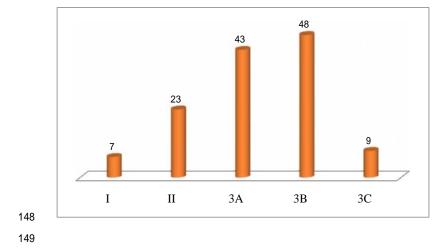

129 78 (60%) of the cases while the femur accounted for 19 (14.6%). Gustilo and Anderson type

- 130 3B [23] was the most common grade of open fracture 48 (36.9%), while type 3A occurred in
- 131 43 (33.1%) as presented in figure 3. The microbial culture shows that *Staphylococcus aureus*
- 132 and *Clostridium perfrigens* were the predominant aerobic and anaerobic isolates.

169 Discussion

170

171 The hospital antibiotic protocol in the Accident and Emergency Department of the hospital, for the treatment of open fractures, has been a combination of ceftriaxone, quinolones 172 173 (ciprofloxacin) and metronidazole-based on findings of Alonge et al. in 2002. The role of 174 early wound debridement and antibiotic administration is recognized as necessary in the 175 management of open fractures in the hospital. Appropriate antibiotic(s) are administered 176 according to the established hospital protocol following the identified historical and 177 sensitivity pattern of wound swabs [24]. The current hospital antibiotic protocol was guided 178 by an earlier study that confirmed *Escherichia coli* as the most common single gram-negative 179 aerobic isolate sensitive to ceftriaxone, quinolones, but since anaerobic organisms were not 180 cultured the inclusion of metronidazole in the hospital antibiotic protocol was based on 181 evidence from other practices. The result of the earlier study in the center was at variance to 182 the findings in this study which showed that Staphylococcus aureus and Clostridium 183 perfrigens as the most common single aerobic and anaerobic isolates respectively. The 184 predominant aerobic gram-positive organism (Staphylococcus aureus) was sensitive to 185 ceftriaxone (CRO), Gentamycin (CN), co-amoxiclav (AMC), cefuroxime (CXM) and 186 amoxycillin (AMX) while the aerobic gram-negative organisms (Escherichia coli and 187 Klebsiella spp) were sensitive to ceftriaxone, amoxycillin, levofloxacin and ceftazidime. The 188 antibiotic sensitivity pattern was similar to the findings by Alonge et al. 2002 and other 189 studies [1][4][5]. Also, anaerobes were significantly sensitive to metronidazole (MTZ) and 190 moderately sensitive to ceftriaxone, levofloxacin, cefuroxime, ciprofloxacin and cefotaxime 191 (CTR), affirming the inclusion of metronidazole in the hospital antibiotic protocol. Since the 192 antibiotic sensitivity pattern from this study is in keeping with findings of an earlier study 193 which results guided the hospital antibiotic protocol, the hospital antibiotic protocol should 194 therefore be retained.

195

196 The organisms cultured in this study showed high resistance to ampicillin (AMP),

197 cotrimoxazole (COT), sulphonamides (SN), clindamycin (CML), rosoxacin (RS),

amoxycillin, cefazolin (CF), and tetracycline (TET). The aerobic gram-positive organisms
 were resistance to ceftazidime (CAZ), cefotaxime (CTR) and metronidazole while the aerobic

were resistance to ceftazidime (CAZ), cefotaxime (CTR) and metronidazole while the aerobicgram-negative microorganisms were resistance to cefotaxime), metronidazole, amoxycillin,

- 201 cefuroxime). The anaerobic organisms also showed significant resistance to co-amoxyclav,
- amoxycillin, gentamycin and Ceftazidime. These findings are comparable to a similar study
- 203 in another African hospital by Sitali and colleagues in 2017 [25].
- 204

205 Apart from antibiotic sensitivity and microbial patterns, the hospital antibiotic protocol is also

206 influenced by the cost and availability of the drugs. In the centre where this study was

- 207 undertaken as well as in most hospitals in the region, availability of some of the antibiotics
- 208 can be challenging. Even when the drugs are available, affordability often becomes another
- 209 challenge as the majority of persons that in the region lives below the WHO poverty line
- 210 [26]. The use of generic forms of these antibiotics, therefore, the norm in the region.

- 211 The value of antibiotics in the treatment of open fractures has been established, but this does
- 212 not substitute for proper wound debridement and adequate skeletal stabilization as an
- essential aspect of open fracture management. The choice of antibiotic should be guided by
- the knowledge of possible contaminating organisms at presentation, but subsequentinfections
- are most likely multiple organisms which should be covered by choice of antibiotics.
- 216 Evidence-based guidelines for prophylactic antibiotic use in open fractures recommend short-
- 217 course, narrow-spectrum antibiotics for Gustilo Grade I or II open fractures and broader
- 218 gram-negative coverage for Grade III open fractures [27].
- 219
- 220 It is worth noting that cultured isolates from a wound especially in the presence of
- 221 biomaterials and biofilms may not be truly representative of the actual organisms causing
- 222 infections. Since an infection engrafted on a biomaterial (thick, adherent biofilm) responds
- 223 poorly to antimicrobial therapy and usually is not cured until the biomaterial is removed, the
- reliance on only antibiotics without appropriate debridement of dead tissue should be with
- 225 caution. Antimicrobials that are chosen from the swab culture results may not be effective
- against all of the bacterial species in these biofilm infections [27]. Incidentally, it takes some
- time before biofilms developed. Since the cultures in this study were all done within seven
- days of admission, the identified sensitivity patterns may not be entirely reflective of the antibiotic sensitivity and resistance in open fractures with chronic wounds where there is an
- existence of biofilms.
- 231

232 CONCLUSION

- 233 The hospital antibiotic protocol which recommends the combination of ceftriaxone,
- 234 quinolones, gentamycin, co-amoxyclav and metronidazole in treating open fractures in the
- 235 Accident and Emergency department, was based on their sensitivity to cultured microbial
- 236 organisms in the hospital. The existing microbial and antibiotic sensitivity patterns had not
- 237 changed significantly over the preceding 12 years when the protocol was established as such
- there is no reason for a change in the current practice.
