ABSTRACT

Land use effect on surface runoff and soil loss:

results of plot-based experiment along east-west

gradient in subtropical China

Surface runoff and soil loss were monitored in six land use types: secondary broadleaved mixed forest (BL), coniferous plantation (CF), extensively managed bamboo plantation (EB), intensively managed bamboo plantation(IB), economic forest(EF) and farmland (FL) in the east (Fuyang, Zhejiang Province), central (Pingjiang, Hunan Province) and west (Muchuan, Sichuan Province) of China. The results showed that (1) there were significant differences of surface runoff among the land use types. The surface runoff and runoff coefficient of FL ranked highest, followed by EB, then CF, IB and EF, with BL as the lowest. The surface runoff and runoff coefficient of FL was about 2-7 times of that of BL. (2) the effects were similar of land use type on the soil loss: the BL had the lowest soil loss, followed by CF, EB, IB and the highest in FL.(3) The characteristics of soil erosion for different land use types were significantly different along the gradient from east to west. The surface runoff coefficient of the different natural conditions, social and economical development stage and the resources investment into soil and water conservation.

1. INTRODUCTION

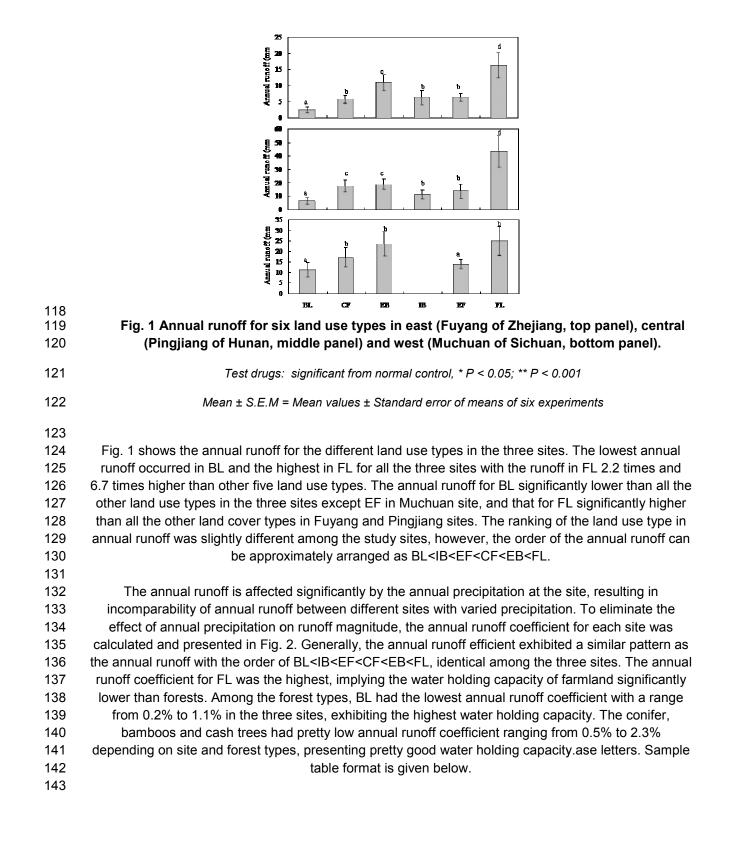

15 Surface runoff and soil loss are important processes of soil degradation, resulting in significant 16 problems to the environment and land productivity [1-2]. Land use type and land cover are considered 17 the most important factors affecting the intensity and frequency of runoff flow and surface soil 18 erosion[3-6]. The climatic factors, especially precipitation, landform conditions and soil conditions 19 have also great effects on surface runoff and soil loss. However, these factors, compared with land 20 use, are uncontrollable or unmanageable artificially. Therefore, land use planning has been given a 21 high priority in soil erosion control in ecologically sensitive areas in China. Studies in a wide variety of 22 environment conditions have shown that surface runoff and sediment yield decrease exponentially as 23 the vegetation cover rate increases[6-9]. Unreasonable land use accelerates soil erosion and 24 consequently, exacerbates environment deterioration and land degradation[10-12] 25

26 The subtropical zone extends from the east coastal area to the west inland area, covering a quarter 27 territory of China. Across this zone, the major land use types are forest land and agricultural land. The 28 agricultural land is mostly covered with annual crops, while forest land is mostly composed of 29 broadleaf forests, conifer forests, economical forests and bamboo forests. The effect of vegetation 30 types on soil and water conservation has been given a great emphasis on sustainable development 31 and ecological construction in ecologically fragile regions. Much work has been conducted to explore 32 the association between land use type and soil erosion control. These researches were traditionally

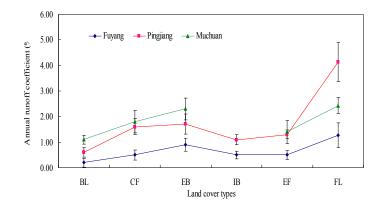

33 confined to one or two major forest types, or other vegetation types. There were also some works 34 focusing on specific location with different land cover types. Extensive assessment to land use effects 35 on soil erosion in large areas may provide overview information[13-15], therefore, to gain insight in the 36 process and to develop strategies for soil and water conservation, more detailed field experimental 37 data that accurately quantify soil loss are needed[16]. 38 39 In our research work, runoff plots were established in selected locations along east-west gradient 40 across subtropical China, and surface runoff and soil loss were monitored for the major vegetation 41 types typical in subtropical region in China, including broadleaf, conifer, bamboo, cash tree and 42 farmland. The primary objective of this study is to quantify the difference in annual runoff and soil loss 43 among different vegetation types along east-west gradient across subtropical China. A second 44 objective is to provide plot-level on-site data for soil loss modeling at regional scale in subtropical 45 China. 46 2. EXPERIMENT SITES AND METHODS 47 48 49 2.1 Experiment sites 50 The work was conducted in three sites along east-west gradient across subtropical China. They were 51 Fuyang of Zhejiang, representing east coastal area, Pingjiang of Hunan, representing central area, 52 and Muchuan of Sichuan, representing west inland area. Their natural conditions are as follows. Fuyang (29°44'-30°12'N, 119°25'-120°19'E) is located in the northwest of Zhejiang Province. The 53 54 landform is mostly mountains or hills with forest coverage of 66.8%. The climate is typical subtropical 55 maritime monsoon, with annual mean air temperature of 16°C, and annual precipitation of 1388mm. 56 Pingjiang (28°25'-29°60'N, 113°10'-114°9'E) is located in the northeast of Hunan Province. The 57 landform is characterized with mountains and hills, with forest coverage of 60.1%. This region belongs 58 to transition zone from central subtropical to north subtropical climate. The climate is continental 59 monsoon, with annual air temperature of 16.8°C and annual precipitation of 1450mm. 60 Muchuan (28°75'-29°08', 103°70'-104°12'E) is located in the southwest of Sichuan Province. This 61 region is also mountainous, with forest coverage of 66.2%. It belongs to typical inland subtropical 62 monsoon climate, mean annual air temperature of 17.3°C and mean annual precipitation of 1332mm. 63 64 2.2 Land use types 65 The major vegetation types in the subtropical region were selected for the study. They were 66 broadleaved mixed forest (BL), coniferous plantation (CF), extensively managed bamboo plantation 67 (EB), intensively managed bamboo plantation (IB), economic forest (EF) and farmland (FL). The 68 dominant species in BL includes Cyclobalanopsis glauca (Fuyang site), Quercus fabric (Fuyang site), 69 Rhododendron stamineum (Pingjiang site), Cinnamomum wilsonii (Muchan site) and etc. BL was 70 mature or pre-mature with the canopy density higher than 0.7. CF includes Cunninghamia lanceolata 71 (Fuyang and Pingjiang) and Metasequoia sequoia (Muchuan site) with the canopy density higher than 72 0.7 also. Bamboo includes Phyllostachys pubescens (Fuyang and Pingjiang) and Sinocalamus affinis 73 (Muchuan site). In EB, the stand density is around 2250 culms per hectare and the averaged diameter 74 at breast height (DBH) between 8 cm and 9 cm for Phyllostachys pubescens. Weeding is 75 implemented periodically but no fertilization. In IB, the stand density is around 2700 culms per hectare 76 and the averaged DBH between 9 cm and 10 cm for Phyllostachys pubescens. Both weeding and 77 fertilization are applied periodically. FL is annual crops including water melon (Fuyang site), peanut

78	(Pingjiang site) and corn (Muchuan site). The topography of all land cover types is similar with a slope					
79	angle of about 20°.					
80						
81	2.3 Runoff plots					
82	Surface runoff and soil loss were measured using the runoff plots. Four runoff plots were established					
83 84	in each land use type across the three sites. Each runoff plot was 5 m in width and 20 m in length with the width side parallel to the contour lines and the length side vertical to the contour lines. The plot					
85	borders were made of brick and cement walls, and were about 15-20 cm above the soil surface to					
86	prevent runoff water from flowing into the plot from the surrounding areas. A collecting trough, 30cm in					
87	depth, 30cm in width at bottom and 50cm in width at top, was constructed with cement at the					
88	downslope end of the plot and covered with a plastic sheet to prevent direct entry of rainfall[17]From					
89	this collecting trough, runoff and eroded sediments were channeled into the collecting tanks. A					
90 01	collecting tank, all 1m in width, depth and length, was constructed at the lower boarder of each runoff					
91 92	plot. All sediment and surface runoff from the plot enter the collecting tank during each rainfall event. Volume of surface runoff was calculated by measuring the height of the water in the collecting tanks.					
93	A sample of 500 ml was taken from the tank after thorough mixing to bring all the sediments into					
94	suspension. The sample was taken to the laboratory where the sediment was filtered, oven-dried at					
95	100°C for 12-24h and weighed. For each rainfall event, runoff volume and sediment loss from the plot					
96	were calculated. One or two rain gauges were placed at each site for rainfall measurement.					
97						
98	2.4 Data analysis					
99	The total annual runoff, annual runoff coefficient and annual soil loss were calculated based on 12					
100	months' monitoring for each runoff plot in the three sites. They were calculated with the Eqs. 1, 2 and					
101	3[18].					
	$\sum_{i=1}^{n} V_{i}$					
102	$R = \frac{\sum_{i=1}^{n} V_i}{S} \times 1000 \qquad \text{Eq.1}$					
102	S S S S S S S S S S S S S S S S S S S					
103	$RC = \frac{R}{P} \times 100\%$ Eq.2					
100	$P = \frac{P}{P}$					
	$\sum_{i=1}^{n} \rho_i V_i$					
104	$SL = \frac{\sum_{i=1}^{J} N^{i}}{S} \times 10$ Eq.3					
	\sim					
105	Where R is annual runoff (mm); RC is annual runoff coefficient (%); SL is annual soil loss (kg/ha.yr); i					
106	is the number of rainfall event through the study period (i=1, 2,, n); Vi is the surface runoff volume					
107	at the ith rainfall event (m3); pi is the sediment content at the ith rainfall event (kg/m3); S is the plot					
108	area (m2); P is the total precipitation during the study period.					
109 110	One-way ANOVA was applied to analyze the annual runoff, annual runoff coefficient and annual soil					
111	loss among different land covers within each site, and different sites for each land use type. Means					
112	were compared using the least significant difference (LSD) test for differences in annual runoff, runoff					
113	coefficient and annual soil loss. Results were considered significant at P < 0.05. Data were analyzed					
114	with SPSS program V.18.

149

150 Surface runoff was affected by many factors including climatic, topographical, petrologic and land use. 151 The factors such as precipitation, soil permeability, slope gradient and length, as well as land cover 152 were considered the most important in controlling the surface runoff generation [19]. At a specific site 153 with similar conditions of topography and pedology, vegetation plays a dominant role in reducing 154 surface runoff. The species composition, vegetation type and spatial pattern are the crucial factors controlling the water holding capacity of soil at a specific site [20] The shrub and herbage are denser, 155 156 and the litter layer is thicker in SB than in other vegetation types, which prevents surface runoff from generating in a short time after precipitation and slow runoff flow when the surface runoff has 157 158 generated[21-22]. Soil permeability is higher in SB than in other vegetation types, resulting in a large 159 portion of subsurface and interflow and reducing surface runoff in SB[23-25] These advantages lead 160 to a lowest annual runoff flow and runoff coefficient in SB. Although the canopy density and trees 161 density was higher in EF and EB, the annual runoff flow and surface runoff coefficient were pretty 162 high. The spatial structure of EF and EB was made simple due to extensive managements, and the 163 ample solar radiation accelerates decomposition of forest litter, reducing the water holding capacity in 164 these forests. The herb and shrub layer and litter layer are usually mostly removed in farmlands, 165 which produces more bare land. Furthermore, the soil is covered by the crops only in growing 166 seasons. All these factors contribute to its limited ability to retain precipitation in farmlands. 167

3.2 Soil loss related to land use types

168 169

3.2 Soli loss related to land use types

Table 1 shows the soil loss of the different land use/vegetation types in the east (Fuyang), central
(Pingjiang) and west (Muchuan) area in subtropical China. The analysis indicates that the soil loss
was significantly different among the land use/ vegetation types. The highest soil loss was found in
the farmland, followed by economic forests, intensively managed bamboo forests and extensively
managed bamboo forests, then by conifer forests and the lowest in secondary broadleaved forests.
The soil loss of the farmlands was 3-9 times of that of the secondary broadleaved forests. All these
data indicate that the forests have higher capacity to resist soil erosion than the farmland.

177

178 Soil erosion is the consequence of interaction between soil and its environment. The influential 179 factors, including the resistance to erosion, erosion force, slope angle and length, land use / 180 vegetation type etc., vary substantially from site to site[19]. Land use /vegetation type regulates 181 reallocation of precipitation and soil permeability and therefore affects sediment production processes 182 driven by precipitation and runoff water. In the secondary broadleaved forests with less human 183 disturbance, the vertical canopy layer of trees, shrubs and herbs increase the spatial structure 184 heterogeneity, more precipitation will be retained by forest canopy and return to air as vapor [26-27]. 185 Furthermore, the forest litter layer is also thick, holding more water and increasing soil permeability. 186 All these factors contribute to high soil surface roughness and resistance to erosion[28-29]. In 187 coniferous plantation, extensively managed bamboo plantation, intensively managed bamboo 188 plantation and economic forest with more management, the canopy spatial structure heterogeneity is decreased and the litter layer is also less thick due to fast decomposition with more solar radiation, 189 190 which can explain their higher soil loss than that of the secondary broadleaved forests. In farmland 191 with highest soil loss, the vegetation cover is sparse and relatively homogenous. Therefore soil 192 surface roughness and soil resistance to erosion are both decreased and consequently sediment 193 production in precipitation processes and the capacity of the surface runoff water to carry sand are 194 both increased which leads to much soil erosion[30-31].

4. CONCLUSION

There was significant difference in surface runoff and runoff coefficient among the land use types. The
surface runoff and runoff coefficient of FL ranked the highest, followed by EB, then CF, IB and EF,
with BL as the lowest. The surface runoff and runoff coefficient of FL was about 2-7 times of that of

220 221

222

BL. There were similar effects of land use type on the soil loss. The BL had the lowest soil loss, followed by CF, EB, IB and the highest in FL. The characteristics of soil erosion from different land use types in the gradient from east to west differed significantly. The surface runoff coefficient and soil loss of the east was significantly lower than that of the west, which may be attributed to the different natural conditions, social and economical development stage and resources investment into soil and water protection.
