# Vegetation Composition Related to Environmental Factors along the International Highway-West Alexandria, Egypt

### ABSTRACT

Roadside vegetation is exposed to a variety of biotic and abiotic stresses that can affect the abundance and distribution of natural vegetation. The present study aimed to characterize the ecological features of the vegetation along the international coastal road from El-Ajami to Ras El-Hekma, West Alexandria, Egypt. The total number of the recorded plant species surveyed in the present study was 84 species (44 annuals, two biennial and 38 perennials) belonging to 74 genera and related to 25 families. Asteraceae, Poaceae, Fabaceae and Chenopodiaceae were the largest families (53.57% of the total species, collectively). Therophytes is the most abundant life forms. The Mediterranean chorotype (58.32%) was the most represented. On the basis of the presence values, the classification of the 84 plant species recorded in 60 stands by cluster analysis yielded four vegetation groups. Group A (47 species) was dominated by *Carthamus tenuis*, group B (39 species) was dominated by *Lactuca serriola*, group C (52 species) was dominated by *Bromus diandrus* and group D (71 species) was dominated by *Suaeda pruinosa*. Calcium carbonate, organic carbon, electrical conductivity, bicarbonate,  $\text{Cl}^-$ ,  $\text{Na}^+$  and  $\text{Ca}^{++}$  showed clear significant differences between groups. The application of Canonical Correspondence Analysis (CCA) showed that, the percentages of porosity,  $\text{CaCO}_3$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{--}$ ,  $\text{HCO}_3^-$  and cations ( $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Ca}^{++}$  and  $\text{Mg}^{++}$ ) are the most effective soil variables. The current study revealed that the coastal sector in Egypt suffers from unplanned development, salt water intrusion and salinization of the soil, so the development of the highway needs a balance between conservation and development.

**Keywords:** Roadside vegetation, Coastal vegetation, Egypt, Multivariate analysis, soil-vegetation relationship

### 1. Introduction

Urbanization and related anthropogenic activities frequently disturb and alter plant composition and directly lead to the degradation of local biodiversity as well as alternation of ecosystem process (Davies and Pullin, 2007; Flory and Clay, 2009). Coastal areas in Egypt suffer from a number of serious problems, including unplanned development, land degradation, excessive erosion rates, water cuts, intrusion of saline water, salinization of soil and degradation of ecosystems (El-Sadek and Ayyad 2000). Therefore, the development of highway infrastructure represents a particularly difficult balance between conservation and development.

The vegetation of the Mediterranean coastal region of Egypt is considered to be one of its major natural resources. Most of these species are therophytes that flourish during the rainy season, giving the coastal belt a temporary showy grassland desert (Zahrán and El-Amier, 2013). Its proper utilization plays a key role in the sound of this region which is known to have enjoyed prosperity during the Graeco-Roman times (Kassas, 1972 and Shaltout, 1983). The western desert of Egypt occurs on the west side of the river Nile. It extends from the

Mediterranean coast in the north to the Egyptian-Sudanian border in the south (about 1073 km), and from the Nile valley in the east to the Egyptian-Libyan border in the west, a width between 600 and 750 km. it covers about 689.000 km<sup>2</sup> that represents approximately two-third of Egypt's area (Zahran and Willis, 2009).

The international coastal highway, connecting the most eastern and western towns in Egypt, was constructed a parallel to the northern coast (El Raey, 1997; Eid and El-Marsafawy, 2002). The human impact is the main factor affecting the abundance and distribution of natural vegetation in the desert (Abd El-Ghani *et al.*, 2013). Moreover, roadside vegetation is exposed to a variety of biotic and abiotic stresses that can affect the composition of plant. Drought, pollution, disease, insects, lack of nutrients, and roadbed management practices may potentially act alone or synergistically to adversely affect plants in proximity to the roadside (Spellerberg, 1998; Jackson, 2000). Therophytes (67%) cover forms the permanent framework of the desert vegetation during rainy seasons, followed by geophytes (11%), halophytes and helophytes, and are the best indicator of the habitat conditions (Stottele, 1995; Zahran and Willis, 2009).

The flora and vegetation of the roadside habitat in Egypt attract the attention of many researchers (Morsy *et al.*, 2008; Abdel Rahman and El Hadidy, 1958; Abd El-Ghani *et al.*, 2013; El-Amier and Abdulkader, 2015). Moreover, the vegetation of the international coast highway from El Arish to Rafah on Sinai coast was studied by Abd El-Ghani and El-Sawaf (2005) and from Port Said to Abu-Qir of Delta coast was studied by El-Amier and Abd El-Gawad (2017). However, the vegetation composition of roadside habitat of the major part of the international coastal highway, northern Egypt, still not studied well. Therefore, the present study aimed to characterize the ecological features of the international coastal road-West Alexandria, Egypt.

## 2. MATERIALS AND METHODS

### 2.1. Study Area

The Mediterranean coastal desert of Egypt (the northern coast) extends from Sallum eastward to Rafah for about 970 km (Zahran and Willis, 2009). The area selected study lies between ~~29° 66'~~ 28° 00' Easting longitude (El-Ajami) and ~~31° 3'~~ 30° 85' Northern latitude (Ras El-Hekma). The sampled stands are distributed in two governorates of Egypt, namely: Alexandria and Marsa Matruh (Figure 1).

The soils of the western Mediterranean coastal land of Egypt are young and essentially alluvial. They are derived from two main sources. The first is Maruit tableland (inland plateau), composed essentially of limestone alternating with strata of limestone and shale, and the second source is beach deposits composed of calcareous oolitic grains (Harga, 1967).

The study area generally falls under the arid Mediterranean type (Zahran and Willis, 2009). The Mediterranean coastal region of Egypt belongs to the warm coastal desert climate. The warmest month in summer has a mean temperature above 20 °C. Occasional short rain storms occur in winter, but most of the days are sunny and mild (Meig, 1973). The floristic elements of the western Mediterranean coastal belt enjoy better climatic conditions than those of the other parts of Egypt.

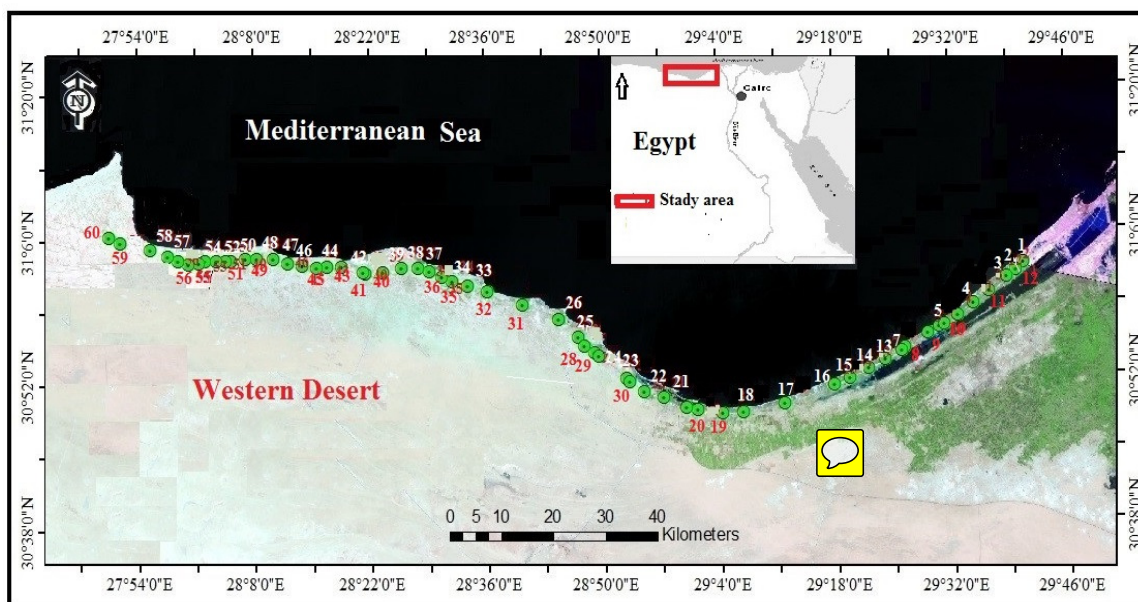

Fig. 1. Map showing the study area.

## 2.2. Vegetation Analysis

A quantitative survey of the roadside vegetation was conducted during the wet season from February to April in 2016. Sixty stands (area = 10×10 m each) were randomly chosen on the roadside of the international coastal highway for sampling vegetation. The density and cover of each species have been estimated in each selected stand according to Shukla and Chandel (1989) and Canfield (1941). Relative values of density and cover were calculated for each plant species and summed up as the importance value (IV). Nomenclature and floristic categories of the plant species within the study area according to Tackholm (1974), Boulos (1999-2005) and Zohary (1966 and 1972). The plant life forms were identified according to the scheme of Raunkiaer (1934).

## 2.3. Soil Analysis

Sixty samples of surface soil were collected as a mixture from 0 to 25 cm in depth. It has been air-dried and sieved to obtain representative sub-samples (fine soil) for physical and chemical analysis. Soil texture, water holding capacity (WHC), porosity, organic carbon and sulphate content were determined according to Piper (1947), while Calcium carbonate content was determined by titration against 1 N NaOH and expressed as a percentage (Jackson, 1962). Electric conductivity and pH were determined in soil-water (1:5) in the manner adopted by Jackson (1962). Carbonates and bicarbonates were determined by titration using 0.1 N HCl (Pierce *et al.*, 1958). Sodium and potassium were determined by flame photometry, while calcium and magnesium were estimated using atomic absorption spectrometer (Allen *et al.*, 1974).

## 2.4. Data Analysis

The cluster analysis (TWINSPAN) of 60 stands and 84 species was performed using the Community Analysis Package program, version 1.2 and Detrended Correspondence Analysis (DCA) into groups according

to Hill and Smilauer (2005). Canonical Correspondence Analysis (CCA) was used to identify the ecological relationships between the vegetation and the environment along the roadside (ter Braak, 1988). Linear correlations coefficient ( $r$ ) was calculated for assessing the relationship between the estimated soil variables. The soil variables for each community were subjected to one-way ANOVA and the mean values were separated based on Duncan's test at 0.05 probability level, using COSTAT 6.3 program.

### 3. RESULTS

#### 3.1. Floristic Analysis

The total number of the recorded plant species surveyed in the present study is 84 species (44 annuals, two biennial and 38 perennials) belonging to 74 genera and related to 25 families (Table 1). The largest families were Asteraceae (18 species), Poaceae (12 species), Fabaceae (8 species) and Chenopodiaceae (7 species). These four families are represented collectively by 45 species (53.57% of the total species). While the other 9 families shared 32.15% of the species and 12 families were monospecific.

According to Raunkiaer (1934) the life-forms of the flora in the present study are grouped under six types as follows: therophytes, geophytes, helophytes, hemicryptophytes, chamaephytes and nanophanerophytes (Figure 2). The majority of the recorded species are therophytes (54.65%) followed by chamaephytes (16.28%) then hemicryptophytes (12.79%) and geophytes, nanophanerophytes (5.81%, each). The lowest value of life-forms is recorded as helophytes which attained value of 4.65%.

**Fig. 2.** Plant life-forms of the recorded plant species in the study area

The chorological analysis of the floristic data reveals that, 49 species (58.32 %) of the total number of recorded species are Mediterranean taxa (Table 2). These taxa are either Pluriregional (18 species =21.42%), Biregional (17 species =20.23%) or Monoregional (14 species = 16.67 %). The other floristic categories are constituted 18 species (14.52%) of the recorded species consisting of Saharo-Sindian (14.29), Saharo-Sindian + Irano-Turanian (5.95), Cosmopolitan (10.71%), Palaeotropical (2.38%) and Neotropical (1.19%).

**Table 1.** Floristic composition and mean of the importance values (out of 200) of the recorded species in the different vegetation group resulted from TWINSpan classification of the study area. ### 3.2. Vegetation Analysis

The application of TWINSpan classification on the importance values (out of 200) of 84 plant species recorded in 60 stands representing the study area, led to the recognition of four vegetation groups (Table 1 and Figure 3).

Group A: It comprises 8 stands dominated by *Carthamus tenuis* with the highest mean importance value (IV = 15.26), the abundant species include *Urtica urens* (IV = 14.31), *Urospermum picroides* (IV = 12.06) and *Cynodon dactylon* (IV = 11.25). The indicator species in this group which attains low IV are *Brassica tournefortii* (IV= 4.53) and *Chenopodium murale* which attained low IV is 0.36 (Table 1). Soil in these stands showed that it has the highest values for many measured soil variables (sand, pH, SO<sub>4</sub><sup>2-</sup> and cations) (Table 3).

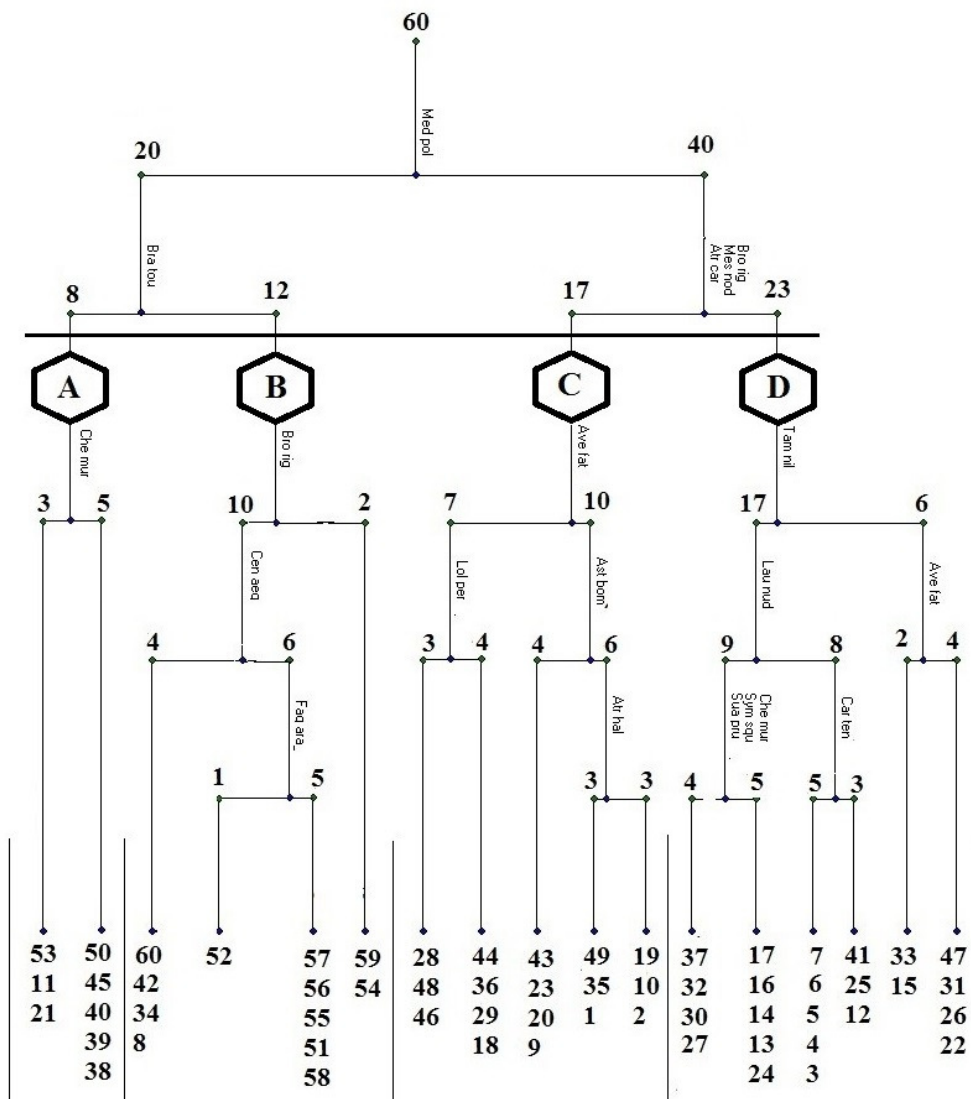

Vegetation group B consists of twelve stands of the studied area dominated by *Lactuca serriola* (IV =22.75). The abundant species include *Onobrychis crista-galli* (IV = 21.41), *Paranochia argentea* (IV = 20.91), *Medicago polymorpha* (IV = 17.34) and *Astragalus spinosia* (IV = 17.31). The indicator species in this group are *Bromus diandrus* (IV = 13.41) and *Centaurea aegyptiaca* which attains low IV is 0.66 (Table 1). The soil of this group was characterized by high content of CaCO<sub>3</sub>, cations and high percentage of silt and porosity (Table 3).

Group C is dominated by *Bromus diandrus* (IV = 20.44) inhabiting 17 stands. The abundant species

include *Mesembryanthemum nodiflorum* (IV = 13.89), *Melilotus indicus* (IV = 10.39), *Atractylis carduus* (IV = 10.20) and *Atriplex halimus* (IV = 9.64). The indicator species in this group is *Avena fatua* (IV=6.17) (Table 1). Most of the examined soil variables in this group (pH, EC, anions and cations) attained their highest levels in the stands of this group (Table 3).

Floristic group D consists of 23 stands dominated by *Suaeda pruinosa* (IV = 10.70). The abundant species in this group include *Cynodon dactylon* (IV = 8.79), *Phragmites australis* (IV = 8.14) and *Fagonia arabica* (IV = 8.01). In this group, the indicator species is *Tamarix nilotica* (IV = 5.15) (Table 1). Soils of the stands of this group were rich in their silt, clay, WHC, OC, Cl<sup>-</sup> and HCO<sub>3</sub><sup>-</sup> (Table 3).

**Figure 3.** Two Way Indicator Species Analysis (TWINSpan) dendrogram of the 60 sampled stands based on the importance values of the 84 species. The indicator species are abbreviated by the first three letters of genus and species respectively.

**Table 3.** Soil variables (mean ± standard error) in the stands representing the different vegetation groups obtained by TWINSpan classification in the study area. WHC: Water holding capacity, OC: Organic carbon, EC: Electrical conductivity.

Significant difference after Duncan's test (P<0.05).

### 3.3. Ordination of Stands

The application of DCA on 60 stands along axes 1 and 2 indicated that the vegetation groups yielded by TWINSpan classification are distinguishable and having a clear pattern of segregation on the ordination plane except groups C and D interconnected (Figure 4). Stands of group A is separated at the upper part of the middle of the DCA diagram. Group B is clear segregated (the right side) along the two axes of DCA. While, Group C is separated the middle part of the DCA diagram. On the other hand, group D is segregated at the lower part of the middle of the DCA diagram.

Fig. 4. Detrended Correspondence Analysis (DCA) ordination diagram of 60 stands of study area.

### 3.4. Soil–Vegetation Relationships

The soil analysis of the represented stands of the four separated vegetation groups indicated considerable significant variations in soil variables (Table 3). The soil texture in all groups is formed mainly of coarse fraction (sand) and partly of fine fractions (silt and clay). Calcium carbonate, organic carbon, electrical conductivity, chloride, bicarbonate, sodium and calcium showed clear significant differences between groups at  $P < 0.01$  and  $P < 0.05$ , respectively. Some other soil variables showed no significant correlation such as soil texture (silt, sand and clay), water-holding capacity, porosity, pH, sulphates, potassium and magnesium.

The correlation coefficient ( $r$ ) between the different soil variables in the sampled stands are shown in Table (4). It has been found that, most soil variables are significant positively correlated with other soil variables. It has been also found that, some soil variables such as sand, pH and  $\text{CaCO}_3$  have significant negative correlation or no correlation with soil variables were shown.

The correlation between vegetation and soil characteristics is shown on the ordination diagram produced by Canonical Correspondence Analysis (CCA) of the biplot of species-environment. As shown in Figure (5), it is clear that, the percentages of sand, clay, porosity,  $\text{CaCO}_3$ ,  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$  and cations ( $\text{Na}^+$ ,  $\text{K}^{++}$ ,  $\text{Ca}^{++}$  and  $\text{Mg}^{++}$ ) are the most effective soil variables, which showed a high significant correlations with the first and second axes of CCA ordination diagram. The dominant (*Lactuca serriola*) and abundant species (*Paranochia argentea* and *Astragalus spinosia*) of group B are separated at the upper right side of CCA-biplot diagram. These species in group B showed a close relationship with sand, porosity and  $\text{CaCO}_3$ . The dominant species (*Carthamus tenuis*) and abundant species (*Urospermum picroides*, *Cynodon dactylon*, *Fagonia arabica* and *Avena fatua*) in groups A, C and D are separated at the upper left side of CCA biplot diagram and no correlation are shown with any soil variables. *Onobrychis crista-galli* and *Medicago polymorpha* as the abundant species in group B are segregated at the lower right side of the diagram. These species exhibited a clear relationship with potassium only. On the other hand, the dominant species (*Bromus diandrus* and *Suaeda pruinosa*) in groups C and D, respectively, and abundant species (*Mesembryanthemum nodiflorum*, *Melilotus indicus*, *Atractylis carduus* and *Atriplex halimus*) of group C as well as *Phragmites australis* as the abundant species in group D are segregated at the lower left side of the diagram. These species exhibited a clear relationship with  $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$  and cations ( $\text{Na}^+$ ,  $\text{Ca}^{++}$  and  $\text{Mg}^{++}$ ).

**Table 4.** Pearson-moment correlation (r) between the soil variables in the stands surveyed in the study area. Por.: Porosity; WHC: Water holding capacity; EC: Electrical conductivity; OC: Organic carbon, ns = not significant at  $P < 0.05$ , \*: Values are significant at  $P < 0.05$ , \*\*: Values are significant at  $P < 0.01$ , \*\*\*: Values are significant at  $P < 0.001$ .

#### 4. DISCUSSION

Roads, being a major human promoter of urbanization, allow for plants to be dispersed by transportation and road building materials. Roads are ecological corridors which support the expansion of a taxon's geographical distribution (Hayasaka *et al.* 2012).

The floristic analysis of the present study revealed that roadside habitat of the international highway comprises 84 plant species, mainly annuals, where the plants were flourished after the rainfall. The Western Mediterranean coastal belt is by far the richest part of Egypt in its floristic composition owing to its relatively high rainfall in the winter season (Zahran and Willis, 2009). Annual plants characterized by high reproductive capacity, as well as ecological, morphological and genetic plasticity (Grime, 1979; Kowarik, 1985).

In association with other relevant studies, Asteraceae, Poaceae, Chenopodiaceae, Fabaceae and Brassicaceae were the major families and also is the most common families in Mediterranean North African flora (Abd El-Gawad and Shehata, 2014; El-Amier *et al.*, 2014; El-Amier and Abd El-Gawad, 2017). Asteraceae is the largest and most widespread family of the flowering plants in the world (Walters and Keil, 1996).

The life-forms of the flora in the present study showed that therophytes are the most represented form, where it may be attributed to their short lifespan, they become abundant only during the rainy season, which enables them to resist the instability of environmental conditions, the Mediterranean climate, topography variation and biotic influence (Ayyad and El-Ghareeb, 1982; Heneidy and Bidak, 2001). Moreover, the relative high frequencies of both chamaephytes and hemicryptophytes in the present study may be attributed to distinct defense against the physiological stresses and ability of these species to resist sand accumulation and grazing (Danin and Orshan, 1990; Danin, 1996). El-Amier and Abd El-Gawad (2017) recorded about 56.95%, 13.25% and 9.93% of therophytes, hemicryptophytes and chamaephytes in the vegetation analysis of the international

coastal highway along north Nile delta. Abd El-Ghani *et al.* (2005) illustrated that chamaephytes were the predominant life form (32%) of the recorded flora of the international coastal highway along El Arish and Rafah, followed by therophytes (31%) and hemicryptophytes (17%). Also, Abd El-Ghani *et al.* (2013) reported that, about 31.15%, 28% and 18% of therophytes, hemicryptophytes and chamaephytes are represented in the vegetation of Qift-Qusier roadside, respectively,

The prevalence of the Mediterranean chorotype of the listed flora in the study area reflects the Mediterranean climate of studied area. This result agrees with most of related studies (Salama *et al.*, 2013; Barakat *et al.*, 2014; El-Amier, 2016; El-Amier and Abd El-Gawad, 2017). Saharo- Sindian and Mediterranean chorotypes accounted for 30.96% of recorded plants. This may be attributed to the fact that plants of the Saharo-Arabian species are good indicators for harsh desert environmental conditions, while Mediterranean species are considered as signal to mesic environment (El-Husseini *et al.*, 2008; Abd El-Ghani *et al.*, 2011). The whole country lies within the Saharo-Arabian belt of the Holarctic floristic realm (Abd El-Ghani *et al.*, 2011). Furthermore, a combination of different floristic elements such as Cosmopolitan, Palaeotropical, Neotropical, Saharo-Sindian and Irano-Turanian are represented by a variable number of species in the roadside environment. This can be attributed to the roadside environments that may be exposed to many potential biotic and abiotic pressures on a plant community as well as the ability of certain floristic elements to penetrate the study area from several adjacent phytogeographical regions (Zahran and Willis, 2009).

The roadside habitat of the international coastal highway dominated with different plant communities. In the present study we determine four communities, two (communities C and D) were the richest and diverse, while community A and B is the smallest and less diverse. In accordance, the ordination of the plant communities showed that clear pattern of segregation on the ordination plane for A and B groups, while groups C and D interconnected, reflecting more similar vegetation structure and environmental variables. Among the identified communities, community D, dominated with *Suaeda pruinosa* and abundant species (*Mesembryanthemum nodiflorum*, *Atractylis carduus* and *Atriplex halimus*) of group C were mainly correlated with salinity, cations and organic matter which could be correlated to the intrusion of saline water and the anthropogenic activities (Abd El-Gawad and Shehata, 2014; El-Amier and Abd El-Gawad, 2017). From my point of view the high species diversity of groups C and D in the study area may be related to the high disturbance of their substrates as a result of agriculture practicing, farming processes and other excessive human disturbances.

Moreover, the vegetation composition of groups A and B in the present study has very much in common with that in Israel (Barbour *et al.* 1981, Tielbörger 1997), and in the middle Mediterranean coast of Egypt (El-Amier *et al.*, 2014; El-Amier and Abd El-Gawad, 2017). Low species presence in these vegetation groups may be related to their high soil salinity. Such salinity stress on species diversity in the study area and related areas was reported by Moustafa and Klopatek (1995); Shaltout *et al.* (1997) and Abd El-Ghani and El-Sawaf (2005).

## 5. CONCLUSION

The present study concluded that, the vegetation analysis of the study area indicates that, the Mediterranean taxa are represented by relatively highest percentage of plant species, and are used as a source for human food, animal fodder and agro-industrial raw materials and for the medicinal purposes. Therefore, the conservation of natural habitats of this coastal desert is vital importance and need judicious utilization for sustainable development.
