

Responses of physiological indices of forage sorghum under different plant populations in various nitrogen fertilizer treatments

Abstract

In order to evaluate physiological indices of forage sorghum in different plant densities and nitrogen levels, an experiment was conducted at Research Farm, Faculty of Agriculture, Islamic Azad University, Isfahan (Khorasgan) Branch, Isfahan, Iran. The main plots were plant densities, namely, 250000, 300000, 350000, and 400000 plants per ha, and four levels of nitrogen, namely, 0, 80, 160 and 240 kg N/ha were sub-plots. The field was under cultivation of barley during the previous winter. For all plant density treatments, from 25 days after plantation until 95 days after planting, the total dry matter trend increased gradually. The highest total dry matter was observed in 95 days after plantation which was related to 400000 plants per ha and 240 KgN/ha. Study the trend of variances of crop growth rate showed that in all treatments, the crop growth rate was low in the beginning of sampling, thereafter increased considerably up to 60 days after planting with a peak in 60 days after planting, then showed a declining trend after that. In all of plant density treatments, RGR decrease during plant growth and reached to a zero at 75-85 days after planting, and it reached into negative after these days until harvesting time. In different plant nitrogen levels, RGR trends also decrease during plant growth and reached to a zero at 40-60 days after planting. The maximum LAI was obtained for 400000 plants per ha and 160 kgN/ha. Study of trend of net assimilation ratio (NAR) showed that in all treatments, the NAR was stable in the beginning of sampling, thereafter showed a declining trend that toward zero (90-95 days after planting).

Keywords= Physiological indices, Forage sorghum, Plant density, Nitrogen.

Introduction

Sorghum [*Sorghum bicolor* (L.) Moench] is a major cereal food crop in many parts of the world (Shahrajabian *et al.*, 2011). Bourke (1984) reported the importance of measuring total dry weight, leaf area index (LAI), and crop growth rate (CGR). Crop growth depends on the ability of leaves to capture and use solar radiation, with that they can provide the energy to drive both CO₂ assimilation and water transpiration processes (Albrizio and Steduto, 2005; Seyed Sharifi *et al.*, 2011). Bavec *et al.* (2007) noted that the most important photosynthesis acceptor-leaf area vary among cultivation measures and it is limited factor for creating exact growth in wheat. Morphological indexes such as leaf area and plant height complement plant growth quantitative analysis and enable the determination of the effects of the use of different crop management

36 techniques (Poh *et al.*, 2011; Shahrajabian *et al.*, 2013). Gordon *et al.* (1997) showed that
37 historically models of leaf area index (LAI) have varied both in their complexity and
38 physiological implications. Growth analysis is a way to assess what events occurs during plant
39 growth (Hokmalipour and Hamele Darbandi, 2011). Growth analysis is a suitable method for
40 plant response to different environmental conditions during life (Tesar, 1984). The determination
41 and growth analysis, interpretation of how species respond to a given environmental condition
42 (Zare-Feizabady and Ghodsi, 2004). To compare the physiological responses of growth, analysis
43 should be independent of environmental changes. For growth analysis, leaf area and dry weight
44 measured parameters are mandatory and growth will follow through mathematical calculations
45 (Paleg and Aspinal, 1981). Factors affecting growth dynamics such as dry matter accumulation,
46 crop growth rate, relative growth rate and leaf area index are important investigations tools to
47 facilitate the development of better agronomic management (Rahimzadeh *et al.*, 2013). Hunt
48 (1982) concluded that total dry matter compensation is influenced by crop growth rate, relative
49 growth rate, relative leaf area growth rate and net assimilation rate. This trial was conducted to
50 evaluate some physiological indices of forage sorghum in relation to different plant populations
51 and nitrogen levels.

52

53 **Materials and methods**

54 The experiment was conducted in 2015 at Research Farm, Faculty of Agriculture, Islamic Azad
55 University, Isfahan (Khorasgan) Branch, Isfahan, Iran (latitude 32° 40'N, longitude 51° 58' E,
56 and 1570 m elevation). The main plots were plant densities, namely, 250000, 300000, 350000,
57 and 400000 plants per ha, and four levels of nitrogen, namely, 0, 80, 160 and 240 kg N/ha were
58 sub-plots. The field was under cultivation of barley during the previous winter, and planting of
59 sorghum was done just after harvesting of barley. In this trial, hybrid of forage sorghum, Speed
60 Feed was used. Speed Feed is characterized by early flowering, early maturation, rapid and high
61 accumulation of dry matter and high resistance to weeds and insects. The field was tilled to a
62 depth of 20 cm. Previous crop was harvested on 21 June and forage sorghum seeds were sown on
63 24 June with skillful workers. Application of nitrogen fertilizer for each treatment was done in
64 two stages (half of it was used before planting and half of it was used before stem elongation).
65 The source of nitrogen fertilizer was urea. According to soil analysis and high amount of P and
66 K, P and K fertilizers were not used. Also, weeds were controlled by hoe weeding. The first
67 irrigation was applied immediately after sowing. Second irrigation was done three days after the
68 first one. The other irrigation intervals were done according to plant 's requirement (10 days).
69 Each plot has six rows, the length and width of each row was 4 and 3 m, respectively. The
70 distances between rows were 50 cm. Row numbers 1, 4 and 6 also upto 50 cm, primer and edge
71 lines were discarded from sampling. Samples were harvested when plants were in 20% of
72 anthesis stage. The variance trend of total dry matter (TDM), leaf area index (LAI), net
73 assimilation ration (NAR), crop growth rate (CGR), and relative growth rate (RGR) were

74 determined with using 1-5 equations (Acuqaah, 2002; Gupta and Gupta, 2005). Data were
75 subjected to analysis by the SAS software and graphs were drawn using Excel program.

76 $W = e^{a^2 + b^2t + c^2t^2}$ (1)

77 $LAI = e^{a^1 + b^1t + c^1t^2}$ (2)

78 $NAR = (b^2 + 2c^2t)e^{(a^2 - a^1) + (b^2 - b^1)t + (c^2 - c^1)t^2}$ (3)

79 $CGR = NAR * LAI = (b^2 + 2c^2t)e^{a^2 + b^2t + c^2t^2}$ (4)

80 $RGR = b + 2ct + 3dt^2$ (5)

81

82 Results and Discussion

83 Total dry matter

84 The influence of different nitrogen levels and plant densities on total dry matter trend was
85 measured from 25 days after plantation until harvesting time. For all, plant density treatments,
86 from 25 days after plantation until 95 days after planting, the total dry matter trend increased
87 gradually. The highest total dry matter was observed in 95 days after planting which was related
88 to 400000 plants per ha (Fig 1). There was significant difference between 400000 plants per ha
89 and other treatments. The minimum total dry matter was related to 250000 plants per ha. Study
90 of trend of total dry matter shows that, this trend also increase slowly from 25 days after
91 plantation until harvesting time. The highest and lowest total dry matter was obtained in 240
92 kgN/ha and control treatment (0 kgN/ha) which had meaningful differences with each other and
93 other treatments (Fig 2). The increase in dry matter is related to accelerating the photosynthesis
94 activity that is caused dry matter accumulation (Seyed Sharifi and Raei, 2011). These scientists
95 also found that the efficiency of the conversion of intercepted solar radiation into dry matter
96 decrease with decreasing of leaf area index. Total dry matter trend (TDM), and crop growth rate
97 (CGR), are the most important traits in plant growth analysis (Hokmalipour and Hamele
98 Darbandi, 2011).

99
 100 **Figure 1.** Total dry matter trend in different plant densities (d1, d2, d3 and d4 are 250000, 300000, 350000, and
 101 400000 plants per ha, respectively).
 102

103
 104 **Figure 2.** Total dry matter trend in different nitrogen levels (n0, n1, n2 and n3 are application of 0, 80, 160 and 240
 105 kg N/ha).
 106

107 **Crop growth rate**

108 The influence of different nitrogen levels on CGR trend has shown, CGR was low at 25 days
 109 after plantation, then the increased up to 50 days was happened. The highest CGR for d1, d2 and
 110 d4 was related to 50 days after plantation and the highest CGR for d3 was obtained in 55 days
 111 after plantation, then all trends decreased sharply (Fig 3). Study the trend of variances of crop
 112 growth rate showed that in all treatments, the crop growth rate was low in the beginning of
 113 sampling, thereafter increased considerably up to 60 days after planting with a peak in 60 days
 114 after planting for N0, N2 and N3, and 55 days after planting for N1, then showed a declining
 115 trend after that (Fig 4). The decrease in crop growth rate towards maturity is due to senescence of
 116 leaves and decrease of leaf area index (Seyed Sharifi and Raei, 2011). Beadle (1987) found that
 117 crop growth rate in early stages due to the complete absence of vegetation and low percentage of
 118 light absorption is lower, but with the rapid increase in the rate of plant growth that occurs

119 because the level of developed leaves and thus absorption of solar radiation increase. Should be
120 noted that negative values of crop growth rate is due to loss of leaves at the end of growing
121 season (Hokmalipour and Hamele Darbandi, 2011).

122

123

124 **Figure 3.** CGR trend in different plant densities (d1, d2, d3 and d4 are 250000, 300000, 350000, and 400000 plants
125 per ha, respectively).

126

127

128 **Figure 4.** CGR trend in different nitrogen levels (n0, n1, n2 and n3 are application of 0, 80, 160 and 240 kg N/ha).

129

130 Relative growth rate

131 In the initial stages of the plant growth the ratio between alive and dead tissues is high and
132 almost the entire cells of the productive organs are activity engaged in vegetative matter
133 production (Seyed Sharifi *et al.*, 2011). In all of treatment compounds, RGR decrease during plant
134 growth and reached to a zero at 75-85 days after planting (Fig. 5), and it reached into negative
135 after these days until harvesting time. In different plant nitrogen levels, RGR trends also decrease
136 during plant growth and reached to a zero at 40-60 days after planting (Fig. 6). Similar
137 observations have been reported by other researchers (Jeffery *et al.*, 2005; Shahrajabian *et al.*,

138 2013). Karimi and Siddique (1991) reported that variation in relative growth rate during the
 139 growth period is decreased, so that the high growth rate in the early period and then decreases.
 140 Relative growth rate of plants depends on environmental factors and genetic characteristics.
 141 Changes in the relative growth rate of plant photosynthesis and respiration changes with time,
 142 and thus, increasing the amount of plant respiration at the end of the period is negative
 143 (Robertson and Giunta, 1994).

144

145

146 **Figure 5.** RGR trend in different plant densities (d1, d2, d3 and d4 are 250000, 300000, 350000, and 400000 plants
 147 per ha, respectively).

148

149

150 **Figure 6.** RGR trend in different nitrogen levels (n0, n1, n2 and n3 are application of 0, 80, 160 and 240 kg N/ha).

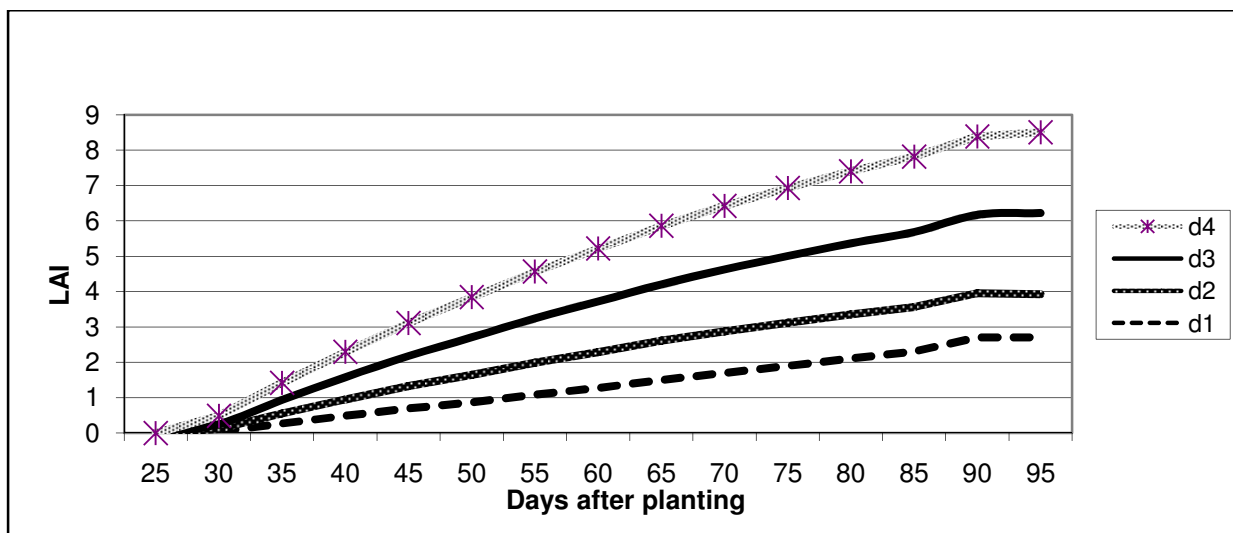

151

152 **Leaf Area Index**

153 LAI trend in all growth and development stages for different irrigation treatments were
 154 measured. Leaf area index increased during plant growth and reached to a maximum level at 90

155 days after planting. From 90 days after planting until harvesting time, leaf area index trend was
 156 steady due to increasing aging leaves, shading and competition between plants for light and other
 157 resources. The maximum LAI was obtained for d4 and N3, respectively. The lowest LAI was
 158 also achieved in d1 and N0 (control treatment). Leaf area index (LAI) is an index of the size of
 159 the photosynthetic system. Seyed Sharifi and Raei (2011) mentioned that increasing leaf area
 160 index is one of the ways of increasing the capture of solar radiation within the canopy and
 161 production of dry matter. Hence, dry matter produced decreases with decreasing of leaf area
 162 index.

163

164

165 **Figure 7.** LAI trend in different plant densities (d1, d2, d3 and d4 are 250000, 300000, 350000, and
 166 400000 plants per ha, respectively).

167

168

169 **Figure 8.** LAI trend in different nitrogen levels (n0, n1, n2 and n3 are application of 0, 80, 160 and 240 kg
170 N/ha).

171

172 Net Assimilation Ratio

173 Study of trend of net assimilation ratio (NAR) showed that in all treatments, the NAR was stable
174 in the beginning of sampling, thereafter showed a declining trend that toward zero (90-95 days
175 after planting). Net assimilation rate (NAR) is an indirect photosynthetic activity. This is based
176 on the principle that the increase in dry weight of plants in a given period is a measure of net
177 photosynthesis. Growth analysis is still the most simple and precise method to evaluate the
178 contribution of different physiological processes in plant development (Seyed Sharifi and Raei,
179 2011). Shahrajabian et al. (2013) also indicated that physiological growth analysis is important in
180 prediction of yield.

181

182

183 **Figure 9.** NAR trend in different plant densities (d1, d2, d3 and d4 are 250000, 300000, 350000, and
184 400000 plants per ha, respectively).

185

186

187 **Figure 10.** NAR trend in different nitrogen levels (n0, n1, n2 and n3 are application of 0, 80, 160 and 240
188 kg N/ha).

189

190 **Conclusion**

191 N nutrient and plant density is still one of the major parameters limiting crop yield, plant growth
192 and productivity. Adequate supply of N to crops is fundamental to optimize crop productivity.
193 Growth analysis is still the most simple and precise method to evaluate the contribution of
194 different physiological processes in plant development. Hokmalipour and Hamele Darbandi
195 (2011) indicated that physiological growth analysis is important in prediction of yield.
196 Understanding physiological basis of forage sorghum in different plant densities and nitrogen
197 levels is critical for the rationale design of agricultural practices. For all plant density treatments,
198 from 25 days after plantation until 95 days after planting, the total dry matter trend increased
199 gradually. The highest total dry matter was observed in 95 days after plantation which was related
200 to 400000 plants per ha and 240 KgN/ha. Study the trend of variances of crop growth rate
201 showed that in all treatments, the crop growth rate was low in the beginning of sampling,
202 thereafter increased considerably up to 60 days after planting with a peak in 60 days after
203 planting, then showed a declining trend after that. In all of plant density treatments, RGR
204 decrease during plant growth and reached to a zero at 75-85 days after planting, and it reached
205 into negative after these days until harvesting time. In different plant nitrogen levels, RGR trends
206 also decrease during plant growth and reached to a zero at 40-60 days after planting. The
207 maximum LAI was obtained for 400000 plants per ha and 160 kgN/ha. Study of trend of net
208 assimilation ratio (NAR) showed that in all treatments, the NAR was stable in the beginning of
209 sampling, thereafter showed a declining trend that toward zero (90-95 days after planting).
